Abstract

Modern software must evolve in response to changing conditions. In the most widely used programming environments, code is static and cannot change at runtime. This poses problems for applications, that have limited down-time. More support is needed for dynamic evolution. In this paper we present an approach for supporting dynamic evolution of Java programs. In this approach, Java programs can evolve by changing their components, namely classes, during their execution. Changes in a class lead to changes in the its instances, thereby allowing evolution of both code and state. The approach promotes compatibility with existing Java applications, and maintains the security and type safety controls imposed by Java's dynamic linking mechanism. Experimental analyses of our implementation indicate that the implementation imposes a moderate performance penalty relative to the unmodified virtual machine.

1 Introduction

Software systems must change over time. Changing business practices, the relentless advance of technology, and the demands of end users drive this evolution. The functionality required of applications inevitably changes in response to these factors. Consequently, in order to remain viable, applications must evolve to meet new requirements. Software component evolution is a major focus of effort in software engineering [30, 41].

The vast majority of commercial software is written in a few imperative languages, such as C++ or Java [3]. For these languages, software evolution is generally a slow, static process. Most of us are familiar with the process of waiting for the latest version of our favorite program to come out, stopping work to install the new version over the old one, then cleaning up the resultant mess of incompatible document formats and lost settings. The fact that a running program cannot be changed drives this cycle. Since any update requires stopping a program and overwriting all or part of it, incremental updates are often impractical, and major updates problematic. For a large class of critical applications, such as business transaction systems, telephone switching systems and emergency response systems, the interruption poses an unacceptable loss of availability.

What is needed, then, is more support for applications that evolve *during execution*. Dynamic evolution provides a number of benefits in addition to easing upgrades to critical software.

Dynamic evolution has applications in software distribution and management. Consider a distributed system in which changes in all active applications are either pulled or pushed from software servers to the active applications. While several applications, for instance Netscape[1] Navigator, Microsoft[2] Internet Explorer and RealAudio[3] RealPlayer, currently support such application-specific updates, most use static updates for modifying applications.

Consider, also, runtime optimization. Often, specific properties of systems are best determined at runtime. For example, many applications can be highly optimized *if* some information about the input is known during development. However, these same optimizations result in specialized code restricted to a smaller input domain. If code can be modified at runtime, a program can accept a wider range of data, yet load and use methods optimized for the current data set.

In a similar manner, dynamic evolution can be very useful in any application whose behavior is driven by a set of policies, such as security policies. For example, dynamic security policies can be implemented using total mediation, without modifying code at runtime. This method requires a security check at every access of every resource [39]; due to the high performance cost, it is not widely used. Systems that employ total mediation implement dynamic policies by using general, static code to interpret dynamic data structures – a computationally expensive process. Dynamic evolution allows designers to move logic from interpreted data structures into directly executed code. This provides the efficiency of code-driven security enforcement [38] without sacrificing flexibility.

In this paper, we present an approach for dynamic evolution of Java programs. While Java [3] provides several mechanisms, such as inheritance, interfaces and dynamic linking, for program extensibility, it does not support true dynamic evolution, in which both the code and state of a program can evolve gracefully. In our approach, Java programs can evolve by changing their components, namely classes, during execution. Java classes can be considered to have a life cycle with three discrete states: unloaded, or *static*, *loaded*, and *active*. Figure 1 depicts this cycle. A static class exists only in storage; it has not been loaded into the Java virtual machine. A loaded class has been loaded and possibly linked. Finally, an active class has live instances and / or methods running. We are concerned with changing active classes; a *dynamic class* can change while active.

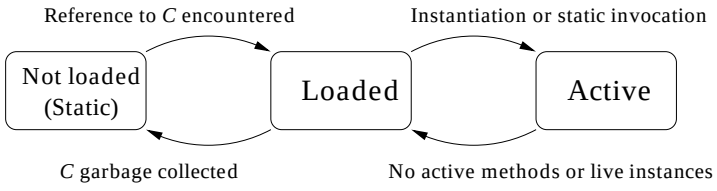

Figure 1: Phases in the life cycle of a Java class, *C*

Before designing the dynamic programming environment, we developed a basic formal model of classes, objects, and the relationships between them. Then, after deciding what types of changes we wanted to support, we defined the notion of class change within this framework. The formalization permits rigorous and convenient analysis and representation of the state of a system before and after a class change; we can formally show that the change model and implementation meet our goals.

We wished to preserve the syntax and semantics of the target language. Doing so ensures compatibility with existing code, and provides greater ease of use as developers do not need to learn new language constructs. This constraint requires that we preserve the type safety characteristics of a program throughout its execution. Type safety encourages the development of safer, more disciplined code. In a dynamic system, type safety can restrict wild, unsound changes, alleviating the dangers inherent in changing code. Further, many of Java's security mechanisms, for instance, separation of user and system name spaces and protection of private data, depend on the type-safe properties of Java programs. Therefore, we impose the restriction that all changes in a program preserve the type safety properties of the program. Section 2.1 presents our formal model, and defines valid class change. Using the formal model, we show that a valid class change preserves type safety.

In order to provide a convenient, backward-compatible interface, and to support changes in any Java class, we extended the Java class loader [32]. This new, dynamic class loader allows a program to define a class multiple times. The dynamic class loader implements changes in a class, and any resulting changes in its instances, in an executing program. We describe this component in detail in Section 2.2.2.

Java is increasingly being used to support distributed programming through code mobility [46]. Although appealing in terms of system design and extensibility [7], systems that support mobility are vulnerable to malicious mobile code. The Java programming environment provides several security mechanisms [13, 17] for protecting hosts from malicious applets. Support for

dynamic evolution, however, raises additional security issues, as malicious applets may use the dynamic class mechanism to modify the classes that enforce specific security policies of a host. Therefore, the dynamic class loader implements a security model that ensures that Java programs can dynamically modify only those resources to which they are authorized. We enforce this policy using name space separation and resource access control. We discuss security in Section 2.3.

We implemented support for dynamic classes by modifying Sun's Java virtual machine (JDK 1.2). Dynamic classes can be implemented in several ways: by changing the language, through library-based support, or by modifying the virtual machine. As stated above, we did not wish to change the language. Library-based support proved to be too awkward and inefficient for our requirements. Thus, we chose to directly modify the virtual machine. Section 3 describes our implementation in detail.

We performed several experiments to measure the performance characteristics of our implementation. The experiments show that dynamic classes add about 6-10% of overhead to Sun's JVM. Further, the cost of updating classes is moderate. Section 4 presents these results, as well as further analysis with regard to alternative methods and related work.

2 Dynamic Classes

In this section, we formally describe the concept of dynamic classes. We begin by presenting a formal model of classes, objects, and inheritance in Java. We consider the potential effects of introducing dynamic classes into a running application. We then use our model to define type-safe dynamic classes. We discuss how best to support dynamic classes while addressing type safety and security issues, and describe our design. In general, we have made conservative design choices, emphasizing compatibility with existing Java code, minimizing performance penalties, and maintaining type safety and overall system security.

2.1 Formal Model

We begin by formalizing the notion of classes, interfaces, inheritance, composition, and dependency among classes in Java. In doing so, we build upon the formal Java type model developed in [10], which includes type widening [9, 42].

2.1.1 Classes and Objects

A type T denotes a set of objects. T is bound to a definition that describes the contents of the objects and operations that act on them. Specifically, this definition consists of T's *interface* and its *implementation*.

Definition 2.1. *(Type interface (*$\mathfrak{i}(T)$*).* The interface of a type T, $\mathfrak{i}(T)$, is a set of public data fields and methods. □

Definition 2.2. *(Type implementation ($\mathfrak{b}(T)$).* The implementation, or body, of a type T, $\mathfrak{b}$(T), is a set of private data fields and a set of method bodies. □

Definition 2.3. *(Interface).* The Java interface construct describes, but does not implement, a type. An interface contains no data fields. □

Definition 2.4. *(Class).* A class describes and implements a type. Thus, a class C is defined by the tuple $<\mathfrak{i}$(C), $\mathfrak{b}$(C)$>$, where $\mathfrak{b}$(C) contains implementations for all methods declared in $\mathfrak{i}$(C). Java supports abstract classes, which provide only a partial implementation. □

Definition 2.5. *(Implements ($\geq_I$)).* The relation $C \geq_I I$ is true if C implements the interface I: $\mathfrak{i}$(I) $\subseteq$ $\mathfrak{i}$(C). □

Definition 2.6. *(Program).* A program is a set of classes. □

A Java class C_1 *depends* on another class C_2 if $\mathfrak{b}(C_1)$ contains references to C_2. The references may include method invocations, field accesses and inheritance. Any change to C_2 may mean that C_1 must change as well [6].

Definition 2.7. *(Dependency ($\propto$)).* The relation $C_1 \propto C_2$ is true if C_1 depends on C_2. Transitivity applies, denoted by $\overset{*}{\propto}$. The dependency relationship applies to specific methods or fields as well. For instance, $C_1.M \propto C_2.N$ is true if $C_1.M$ invokes $C_2.N$. □

Definition 2.8. *(Composition ($\oplus$, $\ominus$)).* $C_1 \oplus C_2$ denotes the union of C_1 and C_2, where C_1 and C_2 are two sets of methods and data. $C_1 \ominus C_2$ denotes their difference; the methods and fields that are defined in C_1, but not in C_2. These operators provide an abstraction for the Java inheritance mechanism. Thus, the Java composition semantics of scoping and overloading are implicit in the definitions of $\oplus$ and $\ominus$. □

We do not define $\oplus$ and $\ominus$ precisely because our focus in this paper is more on examining the effects of dynamic classes.

Definition 2.9. *(Inheritance($\sqsubseteq$)).* The relation $C \sqsubseteq C_S$ is true if C directly extends C_S. Inheritance affects the composition of a class. $\mathfrak{b}$(C) contains the implementations of all of C's superclasses, and $\mathfrak{i}$(I) contains their interfaces. Stated formally:

$$\forall\, T : C \quad \overset{*}{\sqsubseteq} \quad T : \mathfrak{b}(T) \subseteq \mathfrak{b}(C)$$
$$\forall\, T : C \quad \overset{*}{\sqsubseteq} \quad T : \mathfrak{i}(T) \subseteq \mathfrak{i}(C)$$

Transitivity applies, denoted by $\overset{*}{\sqsubseteq}$. Java does not permit recursive inheritance. Thus, $C_1 \overset{*}{\sqsubseteq} C_2 \implies \neg\,(C_2 \overset{*}{\sqsubseteq} C_1)$. Finally, $C_1 \sqsubseteq C_2 \implies C_1 \propto C_2$. Inheritance can apply to both classes and interfaces. Let $\sqsubseteq_C$ specify class extension, and $\sqsubseteq_I$ specify interface extension. $\sqsubseteq$ can refer to either case. □

Definition 2.10. *(Defines: class ($\geq_C$)).* The relation $C_{def} \geq_C C$ is true if C_{def} is the class definition bound to the name C; C_{def} defines C. A $\geq_C$ relationship is not necessarily permanent, but it is singular; $C_{def} \geq_C C \implies \forall\ C_i$: $C_i \neq C_{def}$, $\neg\ (C_i \geq_C C)$. This restriction preserves Java name semantics — a name should only be bound to one value. □

Definition 2.11. *(Instantiation ($\leq$)).* The relation $O \leq T$ is true if the object O is an instance of the class or interface T. $O \leq C \wedge C \overset{*}{\sqsubseteq} D \implies O \leq D$. Likewise, $O \leq C \wedge C \geq_I I \implies O \leq I$. □

Definition 2.12. *(Defines: object ($\geq_O$)).* The relation $C_{def} \geq_O O$ is true iff $C_{def} \geq C \wedge O \leq C$. As with $\geq_C$, $\geq_O$ is not necessarily permanent, and is singular. □

Note that $\leq$ is the transverse of $\geq_O$.

2.1.2 Type Safety Issues

Changing a class C can have a serious impact on type safety. The interface and/or implementation may be affected. Methods can be added, deleted, or modified, and data fields may be added or deleted. Furthermore, the type itself can change. Adding or removing superclasses or interfaces effectively changes the set of types that an instance of C can be cast or assigned to, with potential effects on any variables bound to such an object. Type violations caused by dynamic changes in class definitions fall into two categories: *static* type violations and *dynamic* type violations. The design and implementation of Java contain mechanisms to prevent either from occuring in a static program. Our system must also prevent them from occuring in a dynamic program, due to class changes.

```
public class C { // initial version
    public void foo() {};
}
public class C { // modified version
}
public class D { // dependent class
    public void foo() {
        C c = new C();
        // change C to use new, modified version
        ··· // Code for changing class C
        c.foo();
    }
}
```

Figure 2: Static type violation.

Here we define static and dynamic type violations, and describe how both the standard JVM and our model prevent these violations and ensure type safety. In doing so, we use the notion of the *type set* of a class C, which is the set of all classes and interfaces to which an instance of C can be cast. The type set contains C itself, all classes from which it inherits, and all interfaces that C or one of its superclasses implements.

Definition 2.13. *(Type set ($\tau(C)$)).* Let I_C be the set of all interfaces i such that $C \geq_I i$. Let C_S be C's superclass; $C \sqsubseteq C_S$. Then, $\tau(\mathrm{C}) \equiv \{C\} \cup I_C \cup \tau(C_S)$.
From the definition of instantiation, $O \leq C \implies \forall\ T$: $T \in \tau(\mathrm{C})$: $O \leq T$. □

A static type violation is an invalid field or method reference. For example, if a method in class C_1 references the field $C_2.X$, and C_2 does not contain a field called X, the reference to X is invalid. This type of violation can be detected statically, by examining the source program. The Java compiler and dynamic linker detect static type violations in source code. This mechanism cannot prevent static type violations caused by dynamic class changes. Figure 2 contains code fragments that cause a static type violation. Initially, C's interface has a single public method, `foo()`. A dependent class, D, invokes `C.foo()`. However, it first modifies C, removing `C.foo()` (see Section 2.2.2). The subsequent reference to `C.foo()` is no longer valid.

```
public interface I {
    public void foo();
}
// initial version
public class C implements I {
    public void foo() {}
}
// modified version
public class C {
    public void foo() {}
}
public class D {
    public void foo() {
        I i = new C();
        // change C to use new, modified version
        ··· // Code for changing class C
        i.foo();
    }
}
```

Figure 3: Dynamic type violation.

A dynamic type violation occurs when some event results in a reference being bound to an object of an incompatible type. For example, let O be an instance of C. C does *not* implement the interface I. If O is bound to a variable i of type I, a dynamic type violation results. This type violation cannot be detected statically, since it depends on O. The JVM performs dynamic type checking during operations such as assignment and type casting. If an operation might result in a dynamic type violation, the JVM throws an exception. This type of checking does not always catch dynamic type violations caused by class change, since an assignment might have occurred prior to the class change. For instance, assume that C implements interface I. Let O be an instance of C. Some other object has a reference to O, via i, of type I. If C changes such that it no longer implements I, i's reference to O becomes invalid, since O's type has changed. In this example, i has already been assigned a value. If O's type changes, then any subsequent access to i might cause an error. The only way to prevent such an error would be to type check every object reference instruction, which the JVM currently does not do.

Figure 3 provides an example of a dynamic type violation. Initially, C implements the interface I. Thus, $\tau(\mathrm{C}) \equiv \{C, I, Object\}$. D assigns an object of type C to a variable of type I, a legal action. Then D modifies C such that it no longer implements I; $\tau(\mathrm{C}) \equiv \{C, Object\}$. The reference `i.foo()` causes an error, because the object bound to `i` is no longer of type `I`.

We can now define type safety formally:

Definition 2.14. *(Type safety).* A class C is type-safe if it contains neither static type violations, nor dynamic type violations that cannot be detected by the JVM's runtime type checking. A program P is type-safe if all of its component classes are type-safe. □

2.1.3 Changing Classes Safely

There are two approaches to ensuring type safety during class changes. We could place no constraints on how classes can change, and type check every object reference and method invocation instruction. Or, reduce the necessity for extra runtime type checking by placing constraints on class changes. Various definitions of a valid class change are possible, depending on which approach is used. We have defined a valid class change as one that cannot cause type violations, either static or dynamic.

We chose this approach for two reasons. First, we wished to preserve the type semantics of the Java language. A valid Java program, P, does not contain these type violations. Second, efficiency – type checking all method and object references requires significant CPU time. Our model requires only static checking before a class is modified. No extra runtime type checking is necessary. This approach may appear to have the disadvantage that certain types of evolutionary systems are potentially difficult to specify. However, our constraints relate to dependencies between the classes defined in P. If an active class contains a method M that accesses some field x, and x has been removed, an error *will* result if M executes, and takes the control path along which x lies. The only situation in which it is safe to remove x is one in which M never executes after the change, or the sensitive control path is never taken. In this case, it is a reasonable assumption that M will be removed or modified as well. Thus, if classes are updated in coordination, our constrained definition of class change does not limit potential evolutionary applications any more than does full runtime type checking.

Formally, we define the semantics of class change to prevent static and dynamic type violations, as follows:

Notation: Let $\underline{C}$ denote the definition bound to class C before a change.

Notation: Let $\overline{C}$ denote the definition bound to class C after a change.

Notation: Let ΔC denote the changes made between $\underline{C}$ and $\overline{C}$; $\Delta C \equiv (\underline{C} \ominus \overline{C}) \oplus (\overline{C} \ominus \underline{C})$.

Definition 2.15. *(Dynamic class change ($\mapsto$)).* The operation $\underline{C} \mapsto \overline{C}$ describes a change to C's definition, and is valid if and only if the following two conditions hold true:

1. No class defined in P, where P is the enclosing program, depends on fields or methods being removed from C.
   $\forall\, C_D \in P : \neg\, (C_D \overset{*}{\propto} (\underline{C} \ominus \overline{C}))$

2. An element of C's type set cannot be removed if other classes depend on it.
   $\forall T : T \in \tau(\underline{C} \ominus \overline{C}) : \neg(\exists\, C_D : C_D \neq C \wedge C_D \in P : C_D \propto T)$.

Under these conditions, $\mathfrak{b}$(C) may be changed in any way. Methods and data may be added to $\mathfrak{i}$(C), and removed if doing so does not cause type violations. C's superclass may be changed, and abstract interfaces added or removed as long as types with dependents are not removed from C's type set. Further, $\underline{C} \mapsto \overline{C}$ has the following effects on C subclasses and instances:

1. The change in C's definition is reflected in all subclasses.
   $\forall\, C_D$: $C_D \sqsubseteq C$, $\underline{C_D} \mapsto \overline{C_D}$.
   By the definition of inheritance, $\Delta C_D \equiv \Delta C$.

2. All instances of C change to match the new defintion.
   $\forall\, O$: $O \leq C$, $\underline{O} \mapsto \overline{O}$, where $\underline{C} \geq_O \underline{O}$ and $\overline{C} \geq_O \overline{O}$. See Section 3.2 for more information about this requirement.

□

Note that $C_D \overset{*}{\propto} C$ does *not* mean that C_D must change if C does. If C_D depends on C via method invocation, field access, or aggregation (C_D contains an instance of C), then no change to C_D's definition is implied. We discuss this, as well as other details such as method table updates, further in Section 3.3.

The two conditions for $\mapsto$ preserve type safety. The first condition prevents static type violations, and the second prevents dynamic type violations. No other constraints are needed. After any number of changes, a program is still type-safe. Formally, we state this as a theorem:

Theorem 1. *Given $\underline{P} \overset{*}{\mapsto} \overline{P}$, if $\underline{P}$ is type-safe, then $\overline{P}$ is type-safe.*

We prove Theorem 1 using induction on the number of class changes enacted..

Base step: if no change has been made to P, then P is type-safe. True by the definition of a valid Java program.

Inductive step: If $\underline{P}$ is type-safe, then $\overline{P}$ is type-safe. We prove this using contradiction: we have some $\underline{C} \mapsto \overline{C} \implies \underline{P} \mapsto \overline{P}$, where $\underline{P}$ is type-safe and $\overline{P}$ is not. Therefore, $\exists$ some class $X \in P$: $\underline{C} \mapsto \overline{C} \implies \underline{X} \mapsto \overline{X} \wedge \overline{X}$ is not type-safe. There are two cases:

Case 1: $\overline{X}$ contains a static type violation: $\exists\, Y$: $\underline{C} \mapsto \overline{C} \implies \underline{Y} \mapsto \overline{Y} \wedge X \propto (\underline{Y} \ominus \overline{Y})$. Recall Condition 1, which requires that $\forall X \in P : \neg(\exists\, Y,\ X \propto (\underline{Y} \ominus \overline{Y}))$. This condition contradicts the above.

Case 2: $\overline{X}$ contains a dynamic type violation: $\exists\, C_D : C_D \neq C : C_D \propto T.\ \tau(\underline{X}) \not\subseteq \tau(\overline{X})$. However, $\underline{X} \mapsto \overline{X} \iff \neg(\exists\, C_D : C_D \neq C : C_D \propto T)$ by Condition 2 of $\mapsto$, and we have a contradiction.

Therefore, if $\underline{P}$ is type-safe, then $\overline{P}$ is type-safe. □

2.2 Support for Dynamic Classes

Dynamic classes can be implemented in several ways: (i) by changing the Java language to support mutable classes, as done in [9], (ii) using library-based support, as done with C++ in [21], or (iii) by modifying the virtual machine. We did not wish to modify the syntax or semantics of the Java language. The library-based solution is inefficient and contains intractable implementation problems. In Section 4.3, we describe in detail this solution and its shortcomings. In this section, we describe our design, which uses a modifed virtual machine to provide runtime system support for dynamic classes, and extends the class loader to provide an interface.

2.2.1 Background: Java Class Loader

The interface by which users manipulate dynamic classes is an extended Java class loader. Thus, begin our discussion with some pertinent background on the Java class loading mechanism.

```
public abstract class ClassLoader {
    public Class loadClass(String name);
    protected Class findClass(String name);
    protected Class defineClass(String name, byte[] b, int off, int len);
    protected void resolveClass(Class c);
    ⋮
}
```

Figure 4: Java VM class loader

The JVM resolves references to a class during runtime using a mechanism called the *class loader* [31]. A class loader is responsible for locating the definition of a class, which takes the form of a class file, and loading it into the JVM. A class in Java is, thus, defined by both its name *and* the class loader that loaded it. The JVM defines two kinds of class loaders: the system class loader and user-defined class loaders. The system class loader is the default class loader used for locating and loading system classes and user-defined classes. Users can override the behavior of the default class loader by defining their own class loaders. To build a specialized class loader, the user must extend the abstract base class `ClassLoader`. Figure 4 depicts part of the interface of `ClassLoader`, as well as the methods that can be overriden in user-defined subclasses.

Applications can define multiple class loaders, each maintaining its own namespace of classes. In JDK (Java Development Kit) 1.2, the preferred method of extending `ClassLoader` is to redefine `findClass` to load classes from a new source or take other appropriate action. For example, an extended class loader could download a class file from a network, then call `defineClass` to convert the raw byte array into a class object which it then resolves and uses – web browsers use this method when downloading applets. The code sample in Figure 5 shows how an application can instantiate `MyClassLoader`, a custom class loader, and use it to load `myClass`. `MyClassLoader` then loads any classes referenced in `myClass`.

```
public int main() {
    // make new class loader
    MyClassLoader myClassLoader = new MyClassLoader; // make new class loader
    // use it to load appClass, which implements Runnable
    Runnable app = (Runnable) myClassLoader.loadClass(``appClass'').newInstance();
    // run app - all classes loaded by app will use myClassLoader
    app.run();
}
```

Figure 5: Using a custom class loader

We now describe how the JVM invokes both system and user class loaders [25]. Assume that class B contains a reference to class C. To link in C, the JVM takes several steps. First, it invokes B's class loader, L_B, to load C. If L_B has not already loaded C, L_B.`loadClass` *delegates* the request to its parent class loader, say L_P, via L_P.`loadClass`. If L_B has no parent class loader, it calls the system class loader. Then, if L_P cannot find C, L_B calls its `findClass` method. If this succeeds, the class is loaded. Otherwise, L_B throws a `ClassNotFoundException`.

Creation and use of new class loaders is overseen by the Java security manager [16, 17]. The `ClassLoader` constructor makes a call to `SecurityManager.CheckCreateClassLoader`, which throws a `SecurityException` if the local security policy does not permit creation of new class loaders. Essentially, the JVM uses a hierarchy of class loaders from the system loader to various levels of extended class loaders defined by the application. Security might be compromised if arbitrary user code – such as a downloaded applet – could load system classes with its own untrusted class loader. Therefore, the JVM enforces the constraint that each class loader deal only with classes in its own namespace. System classes are loaded only by the system class loader, which is part of the runtime system.

2.2.2 The Dynamic Class Loader

The programming interface for dynamic classes is the *dynamic class loader*. This class, `DynamicClassLoader`, extends the JVM class loader and, in addition, supports replacement of a class definition, and update of objects and dependent classes. Any class loaded by an instance of `DynamicClassLoader` is automatically a dynamic class.

We chose this approach for several reasons. Since the class loader loads, stores, and examines class definitions, it is a logical choice for a module that modifies class definitions. The design extends Java's dynamic linking mechanism, instead of replacing it. Thus, it supports existing code, with little or no modification. Users can choose to use dynamic classes when and where they see fit. Most importantly, our design preserves the security mechanisms inherent to the class loader system, which include namespace separation and bytecode verification.

The dynamic class loader loads classes from disk in the same manner as the system class loader. It complies fully with the specified semantics of a Java class loader, as described above

```
public class DynamicClassLoader extends ClassLoader {
    public Class reloadClass(String newc);
    public final int replaceClass(String oldc, Class newc);
    ⋮
    // several overloaded versions of replaceClass are defined for convenience
}
```

Figure 6: `DynamicClassLoader` interface

in Section 2.2.1. However, the dynamic class loader provides additional methods that can reload an active class and replace it with a new version. Using runtime system support, these methods implement the semantics of class change ($\mapsto$) as stated in Definition 2.15.

These new methods are `reloadClass` and `replaceClass`. Method `reloadClass` is similar to `loadClass` in that it reads a designated class file from the disk, creates a class object, and returns it. However, `loadClass` does not load classes that are already defined in the system, whereas `reloadClass` succeeds whether the target class was previously defined or not. Given $\overline{C}$, `replaceClass` defines $\overline{C}$ to be the new definition of C, and initiates instance update. These rely on several native methods that interface with the VM's internal data structures. We provide relevant implementation details in Section 3. Figure 6 summarizes the interface to `DynamicClassLoader`.

Users can extend the dynamic class loader by redefining `reloadClass` or `findClass`. Method `replaceClass` is a `final` method and cannot be overridden. This ensures consistent class redefinition and security, as `replaceClass` performs verification of $\overline{C}$, and enforces namespace constraints.

2.3 Security

In Java 1.2, the JVM prevents static classes from performing forbidden actions by using bytecode verification, supporting namespace partitioning, and enforcing user-defined access control policies. The bytecode verifier examines each class before loading it into the JVM, checking for type violations and other illegal operations. Figure 7 depicts a typical namespace configuration in a system that hosts mobile, untrusted applets, such as a web browser. Applets are each run in their own namespace, defined by separate class loaders. Resource classes provided by the host are placed in another namespace Access between namespaces is only permitted `down` the tree; applets are effectively isolated from one another. Furthermore, the user can specify access control policies for more fine-grained protection. In Sun's JDK 1.2 security model, the class `AccessController` acts as a security monitor [2, 16, 17]. All protected resources must call `AccessController.check()`, which checks the

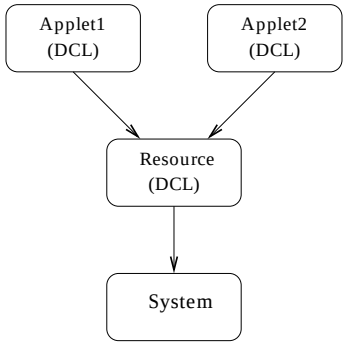

Figure 7: Typical namespace configuration. `DCL` indicates a dynamic class loader.

```
public class myResource { // original version
    public static void foo() { // protected resource method
        // perform security check
        accessController.check(new myResourcePermission());
        // access sensitive resource
        ⋮
    }
}
public class myResource { // weakened version
    public static void foo() { // method now unprotected
        // skip security check...
        // access sensitive resource
        ⋮
    }
}
public class com.evilDomain.evilApplet extends Applet { // malicious mobile applet
    public void start() {
        // get handle to dynamic class loader
        DynamicClassLoader dcl = getClass().getClassLoader();
        // get a URL class loader, linked to originating, evil host
        URLClassLoader ucl = new URLClassLoader(``evil.domain.com'');
        // use it to load a weakened version of the resource class
        Class wr = ucl.loadClass(``myResource'');
        // now use dcl to replace protected resource with weakened version
        dcl.replaceClass(``myResource'', wr);
        // invoke resource, which should be denied but won't be
        myResource.foo();
    }
}
System security policy:  only allow local namespace access to resource
grant codebase ``localhost'' {
    permission myResourcePermission;
}
```

Figure 8: Using dynamic classes to bypass access control.

access against the permissions specified in the security policy. Although the security policy, and thus permissions, can change, the set of protected resources is static.

Dynamic classes pose new security hazards. Malicious code could potentially bypass many existing security mechanisms, by modifying either itself or the protected classes it targets. Specifically, a malicious class could modify itself in order to perform forbidden actions, or modify sensitive classes to either perform or allow forbidden actions. Consider, for instance, Figure 8. A host provides a resource, `myResource`, to which access is restricted via an access control policy. A malicious applet, `evilApplet`, contains code that replaces the protected resource with a new version that does not invoke the access controller. `evilApplet` can then gain access to which it is not entitled.

We do not wish dynamic classes to introduce any new security risks. Therefore, we ensure

```
grant codebase ‘‘localhost’’ {
    permission ucd.pdclab.dynclass.modifyClassPermission;
}
```

Figure 9: Grant class modification privileges *only* to classes in the local codebase.

that Java's security mechanisms extend to dynamic classes, which must adhere to the constraints imposed by this system. This requires several measures.

The dynamic class loader subjects all modified classes to bytecode verification before loading them into the JVM, so a malicious class cannot instrument itself to include illegal bytecode operations. The dynamic class loader honors the separation between namespaces by replacing only those classes defined within its own namespace. Returning to Figure 7, let `DCL` denote a dynamic class loader. Thus, applets and resources are dynamic classes. An applet running in namespace `Applet1` cannot use its own class loader to replace a class defined in `Applet2`. The scenario depicted in Figure 8 cannot happen.

These steps do not, however, prevent a malicious applet in `Applet1` from invoking the *resource* namespace dynamic class loader and modifying resource classes. Thus, dynamic class loaders should be protected by an access control policy. Figure 9 contains a simple example of such a policy: only classes from the local codebase, or namespace, can invoke the dynamic class loader. Applets are excluded. `DynamicClassLoader` contains appropriate calls to the access controller, as described in earlier. Under this policy, applets in Figure 7 cannot modify system or resource classes, nor can they modify themselves. A similar policy could provide full protection for `myResource` in Figure 8.

In practice, it is possible to violate Java's type model and compromise security [40]. This is due to problems in the semantics of dynamic linking and the implementation of the virtual machine. The issue does not bear directly upon dynamic classes, and we do not address it.

Another compelling question is that of the security behavior of the program itself – what resources are accessed, interactions with security monitors other security-related components, how control flow passes through various security domains, etc. Ideally, we could ensure that the security behavior of $\overline{C}$ is no weaker than that of $\underline{C}$; that is, that no potential security holes are introduced into the code. This problem is impossible to solve, in the general case. Conceivably, heuristics could be used, together with assumptions about or constraints on program behavior, to solve the problem for specific cases. Such heuristics are, however, beyond the scope of this paper. It remains the responsibility of the programmer to maintain security behavior across changes.

2.4 Sample Applications

Below, we describe two applications that use dynamic classes. These examples demonstrate how to use the dynamic class loader's interface. They also show how dynamic classes can be applied to provide new functionality in security and software distribution.

Figure 10 contains a simplified excerpt from one of our applications. We extend the Java access

controller, described in Section 2.3, to support dynamic security policies by instrumenting the code of protected classes.

Our application adds dynamism by supporting the addition of protection code to a resource at runtime. The method `DynamicPolicyFile.protectClass(C)` reloads the target class *C* and adds the access control invocation to the beginning of each public method. Then, it redefines *C* to use the new, modified class object.

```
public class DynamicPolicyFile extends java.security.PolicyFile {
    public void protectClass(String C) {
        // Object.getClass() returns class definition of this object;
        // Class.getClassLoader() returns class loader used to load it.
        // for this example we assume that a DynamicClassLoader
        // is always used to load a DynamicAccessController.
        DynamicClassLoader myLoader = getClass().getClassLoader();
        // reload target class
        Class newc = myLoader.reloadClass(C);
        // instrument code via native method
        // which adds call to accessController.check() to each method
        addProtectionCode(newc);
        // switch definition of C to new version
        myLoader.replaceClass(C, newc);
    }
    private void addProtectionCode(Class);
}
```

Figure 10: Dynamic access control example

Figure 11 provides another example, this time part of a dynamic software distribution system. A client application can use `ClassUpdateThread` to dynamically apply class version updates from a remote server. Given a dynamic class loader (`dcl`), `ClassUpdateThread` listens for the update signal from the server. The signal contains the name of the class to update (`cname`). `ClassUpdateThread` then downloads the new class object using a URL class loader. Finally, it replaces `cname` in `dcl`'s namespace with the new version.

The class update server constantly polls for new class files on its disk. Whenever it detects a new version, it sends the name of the updated class to all of its clients. It must also support requests from URL class loaders on the clients. This code does not directly use dynamic classes, so we omit it.

3 Implementation

`DynamicClassLoader` requires virtual machine support for reloading a class definition, finding and updating dependent classes, and finding and updating instances of modified classes. We have modified the Solaris version of Sun's JVM (JDK 1.2). Much of our discussion here pertains

```
public class ClassUpdateThread extends Thread {
    DynamicClassLoader dcl;
    URLClassLoader ucl;
    ClassUpdateThread(DynamicClassLoader _dcl) {
        dcl = _dcl;
        ucl = new URLClassLoader(``updateserver.pdclab.cs.ucdavis.edu'', dcl);
    }
    void run() {
        DatagramSocket s = new DatagramSocket(``6555'');
        byte[] buffer = new byte[512];
        String cname;
        Class cobj;
        while(true) {
            s.receive(buffer, buffer.length); // listen on socket for update signal
            cname = new String(buffer); // get name of class to update
            cobj = ucl.loadClass(cname); // use URL class loader to load from remote host
            dcl.replaceClass(cname, cobj); // activate new version in current namespace
        }
    }
}
```

Figure 11: Dynamic class update client.

specifically to that VM. Our implementation includes a shared library containing functions that support class replacement and instance update. We have also made minor changes in some data structures and functions internal to the JVM to support the library functions. In the remainder of this paper, we refer to this modified, dynamic classes-enabled virtual machine as DVM.

Adding support for dynamic classes requires understanding and manipulating the JVM's internal data structures and functions in several areas. The JVM uses several optimization techniques to increase performance, and we take this into account in our design. In this section, we first provide necessary background on the JVM, then discuss our implementation.

3.1 Background: Java Virtual Machine

Here we describe the general architecture of the JVM. We focus only on those aspects of the architecture that are relevant to to support for dynamic classes. Specifically, we describe JVM's runtime memory organization, the structure and function of class definition objects, and optimizations within the bytecode interpreter.

3.1.1 Execution of Java Programs

Java programs are composed of classes, each of which is stored in a separate class file. A class file contains the types and definitions of fields and methods defined in the class. All references to classes, fields, or methods are symbolic and contain enough information to allow the JVM to link classes in a type safe manner.

The JVM executes a Java program by loading the class associated with the program and interpreting the static method `main()` of that class. A user executes a Java program, say `HelloWorld`, by executing a command of the form `java HelloWorld`. The operating system creates a process and starts execution of the `java` program, which invokes `java_main()` in the main library `libjava`. `java_main()` performs many tasks: it parses command line arguments, initializes the virtual machine data structures and initializes the main thread. Finally, it loads the class named on the command line and calls that class' static `main()` method.

Java method code consists of what is commonly called *bytecode*. Bytecode consists of single-byte opcodes followed by varying numbers of operands. The bytecode instruction set of the JVM is designed specifically to provide support for high-level operations such as method invocation, field accesses, exceptions, and monitors.

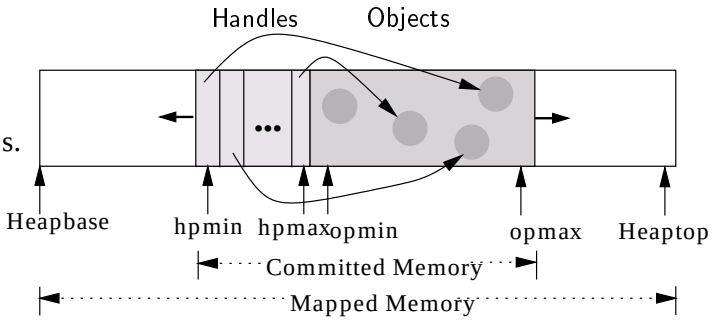

Figure 12: Organization of the Java heap within JVM

The core of the Java interpreter, `ExecuteJava()`, is a loop with a large switch statement that executes bytecode instructions. Execution is entirely within `ExecuteJava()`, except when interpreting the above mentioned high level instructions. These may require other components of the JVM, such as the class loader.

The JVM also includes the ability to invoke non-Java methods. These native methods are implemented as C or C++ functions. Many of the methods in the core Java class libraries are implemented as native methods. They are used whenever it is necessary to do perform functions not supported by Java bytecode instructions, such as I/O.

3.1.2 Java Heap Organization

All Java objects are allocated within a data structure known as the Java heap. In many JVM implementations, including JDK 1.2, the heap is divided into a handle pool and an object pool. Java objects are never addressed directly, only through their handles. The use of handles facilitates garbage collection. When an object is moved, only the pointer in its corresponding handle needs to be updated; the handles never move. Figure 12 shows how a basic contiguous heap is implemented.

This model is very useful when handling object update for dynamic classes, as described in Section 3.2. The DVM can allocate new space for an object when updating it, without changing the handle used to reference the object.

3.1.3 Class Objects

A class object, an instance of `Class`, is created for each loaded class. This object contains the entire class definition, including field types, method signatures and bytecode, and inheritance information. Class objects are special in that they are allocated on the Java heap, but some fields contain pointers into the interpreter's C++ heap. Thus, the code segment for an executing program is distributed among several Java class objects. All names – or classes, methods, fields, etc. – used by the class are stored in the constant pool. In the bytecode, indices into this constant pool are used as symbolic references. Our implementation uses the semantic information contained in class objects to assess dependency relationships and other data, as described in Section 3.3.

3.1.4 JVM Optimizations

The JVM performs several optimizations that can obfuscate internal data structures and cause problems during class changes. These optimizations include the use of method tables, inlining, quick instructions, and direct referencing. Below, we describe the problems that the optimizations raise during dynamic class implementation and how we resolve them.

Each class data structure contains method and field tables used by virtual method calls and other instructions. These tables contain the names of all methods or fields defined within a class *C* and its superclasses; each entry has a pointer to the method body or field visible in *C*'s scope. When changing *C*, the DVM rebuilds the method tables in *C* and all of its subclasses.

When a class is first loaded, its constant pool contains symbolic references, and its bytecode contains indices into the constant pool for all method and data access instructions. The first time the JVM encounters any such instruction, it checks if the constant pool entry has been resolved, and resolves the entry if needed. Then, the JVM changes the instruction to a special *quick* instruction that does not perform the check. Any subsequent execution of that instruction is relatively fast. Certain quick instructions contain offsets into objects or method tables that may change when a class is modified. To make class updating cleaner, the DVM only uses quick instructions that do not contain any offsets or direct references. This avoids the need to update bytecode, but incurs a slight performance penalty.

JDK 1.2 includes a Just-in-Time (JIT) compiler [24]. JIT compilers provide a significant speed boost to a Java VM by generating native machine code from Java bytecode on the fly. This optimization has an impact on dynamic classes – if a method is modified, previously generated machine code becomes invalid. Therefore, if the JIT compiler is enabled, the DVM must ensure that any modified methods are recompiled. We have not yet implemented this step. At present, the JIT compiler is disabled within the DVM.

The JVM also performs inlining, where some method invocation instructions are replaced by the actual bytecode of the method called. This technique also affects dynamic classes, as inlined code may be invalidated by a class change. We have, therefore, disabled method inlining for all classes loaded by a dynamic class loader. System classes and non-dynamic classes are inlined as

usual. We plan to re-enable inlining for dynamic classes by forcing a recompile of any methods that contain inlined code for methods that have changed.

3.2 Updating Instances

There are several alternatives for handling existing instances when a class changes: none, some, or all of them can change to match the new definition. We discuss the options, and justify our decision to enforce global update. Then, we address the implementation details involved in finding, locking, and updating the objects.

3.2.1 Instance Update Models

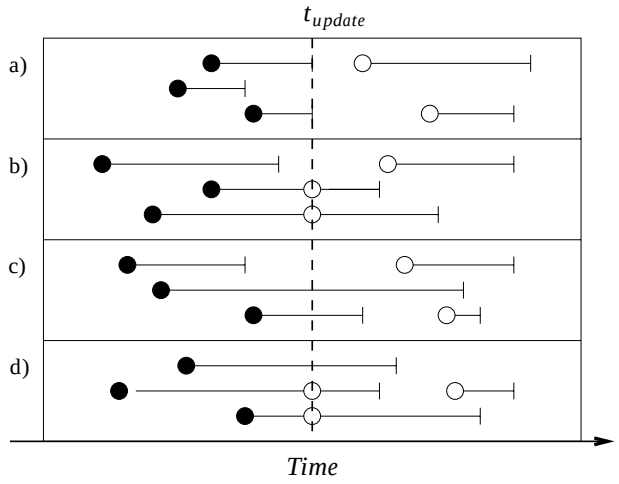

Figure 13: Object update models: (a) version barrier, (b) global update, (c) passive partitioning, and (d) active partitioning.

Possible models for instance update include a version barrier, passive partitioning, global update, and active partitioning. We describe and compare these models here.[4]

First, the DVM could use a barrier on object versions. With this solution, $\underline{C} \mapsto \overline{C}$ cannot occur until all objects defined by $\underline{C}$ have expired, as shown in Figure 13(a). Note that, in this case, t_{update} is delayed until all old objects have expired. This solution lacks the flexibility we desired. Effectively, active classes cannot change.

Another possibility is passive partitioning, where objects created before $\underline{C} \mapsto \overline{C}$ are unchanged, and any created afterwards reflect the new type. Figure 13(c) depicts this model. In this case, as with the previous, multiple definitions of a class can be active simultaneously. This breaks the Java name-binding semantics, and introduces ambiguity that we wished to avoid.

Active partitioning allows the user to actively select which objects to update and which to leave at the previous version, thus partitioning the objects into type spaces. Such a model effectively implements fully dynamic typing, as one could redefine classes at the granularity of individual objects, giving each object its own dynamic type descriptor. Figure 13(d) illustrates this model. As discussed in Section 2, we chose not to make such a drastic change in Java's type system.

Therefore, our model uses the fourth method: global update of all objects defined by C, shown in Figure 13(b). We defined $\mapsto$ (see Definition 2.15) such that the DVM must locate and update all instances of C and its subclasses to reflect the new definition, $\overline{C}$.

[4]Our definitions of version barrier, passive partitioning, and global update, as well as Figure 13(a,b,c), are based on [21].

3.2.2 Implementing Incremental Global Update

Once the DVM has determined that a modified class's instances must be updated, the problem remains of actually locating and processing them. This problem is similar to that of garbage collection. In both cases, there are three major steps: find relevant objects on the heap, lock them, and process them. Therefore, we looked at work in garbage collection [47] when designing our solution.

Garbage collection algorithms generally fall into one of three categories: basic, incremental, and generational [47]. Basic algorithms use techniques such as reference counting or mark and sweep to identify and process objects in a single transaction. This transaction is atomic in that all other threads must block while garbage is collected, and has the undesirable effect of temporarily halting program execution. Incremental algorithms interleave garbage collection with program execution, alleviating the pause effect. Generational algorithms exploit temporal locality in memory usage to optimize garbage collection. We required a more efficient method than a basic algorithm, and generational algorithms rely on assumptions about program behavior that may not apply to instance update. Therefore, we chose an incremental mark-and-sweep approach to updating. In this method, there are two phases: the *mark* phase, during which objects are identified, and the *sweep* phase, in which they are actually updated. The mark phase is atomic, and the sweep phase proceeds incrementally.

In the mark phase, the DVM finds the objects by scanning the handle pool, looking for instances of C. When it finds one, the DVM sets a bit in the object header to indicate that the object needs to be updated. Finally, the DVM modifies the class object pointer present in the corresponding handle structure to point to the new definition, $\overline{C}$. The mark phase eliminates the need to check all object references, thus increasing overall efficiency – the DVM only traps references when updates are pending.

In the sweep phase, the DVM incrementally updates marked objects. To maintain the heap in a consistent state, the DVM traps all accesses of marked objects. If any objects need to be updated, the DVM checks the update bit of the target object when interpreting an object reference instruction. It may seem that this sweep technique implements version partitioning (Figure 13(c),(d)), in that old and new versions may actually be present on the heap at the same time. However, the implementation guarantees that any old object will be update *before* it is referenced. The state of an inactive object does not matter. An advantage of this technique is that the DVM does not update objects destined for garbage collection. The disadvantage is a slight performance cost.

The DVM takes several steps to update an object O. Since other threads may be active, it first locks O to prevent race conditions. Then, processing may continue. The DVM allocates a new object $\overline{O}$, where $\overline{C} \geq_O \overline{O}$, and copies $\underline{O}$'s data to $\overline{O}$. It initializes any *new* fields within $\overline{O}$ to zero (`null`), then switches the handles of $\underline{O}$ and $\overline{O}$. Any references to $\underline{O}$ now point to $\overline{O}$, and O is reclaimed by the garbage collector. Finally, the DVM unlocks O, and the method that triggered the update may continue.

Figure 14 illustrates this process, depicting the structure of the heap before and after a class is

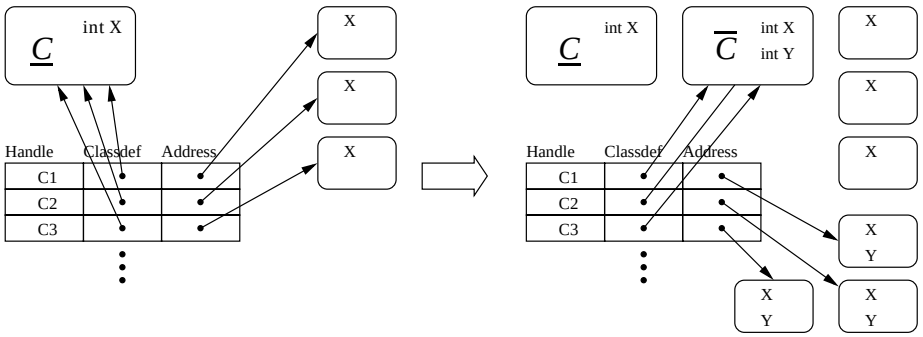

Figure 14: Heap structure before and after replacement

replaced and its instances updated. Initially, the objects $C1$, $C2$, and $C3$ are defined by $\underline{C}$, and their data reflects $\underline{C}$'s fields. When the DVM replaces $\underline{C}$ with $\overline{C}$, $\underline{C}$ becomes inactive. The DVM updates C's instances as they are accessed. After they are all updated, the objects are defined by $\overline{C}$, and have new data fields, which are initialized to zero.

We considered allowing the user to specify a transform function for C, which could assign meaningful values to new data fields, and translate any old data fields that have been given a new type. The DVM would invoke this transform function on each object immediately after updating it, and before returning control to the accessing thread. We rejected this option for the current implementation because it violates the atomicity of object update, and also due to the semantic issues raised by a method that should be able to access both old and new version of the class definition.

3.3 Updating Dependent Classes

When redefining C, the DVM changes the state of all dependent classes to enable C's new definition. This process requires several steps. First, the DVM identifies all dependents and categorizes them by their relation to C – subclass, method usage, etc. It re-resolves all dependent classes, and updates additional information within subclasses.

The DVM identifies dependent classes by scanning the constant pools of all loaded classes for C. Then, it updates each one according to its relation to C. Figure 15 depicts this process at an abstract level. When a class is first loaded, its constant pool contains symbolic references to other class objects and their methods and fields. When the JVM resolves the class, it replaces these references with actual pointers to the referenced object. When the DVM redefines C, any pointers to $\underline{C}$ become invalid, and the DVM replaces all resolved references with the original symbolic references. It then resolves the class and replaces the references with pointers into $\overline{C}$. To support restoration of symbolic references, we added an additional field to the class object structure that contains the original constant pool.

C's subclasses require additional processing. If any data or methods are added to C, the DVM updates the method and field tables of all subclasses. It rebuilds these tables when it re-resolves

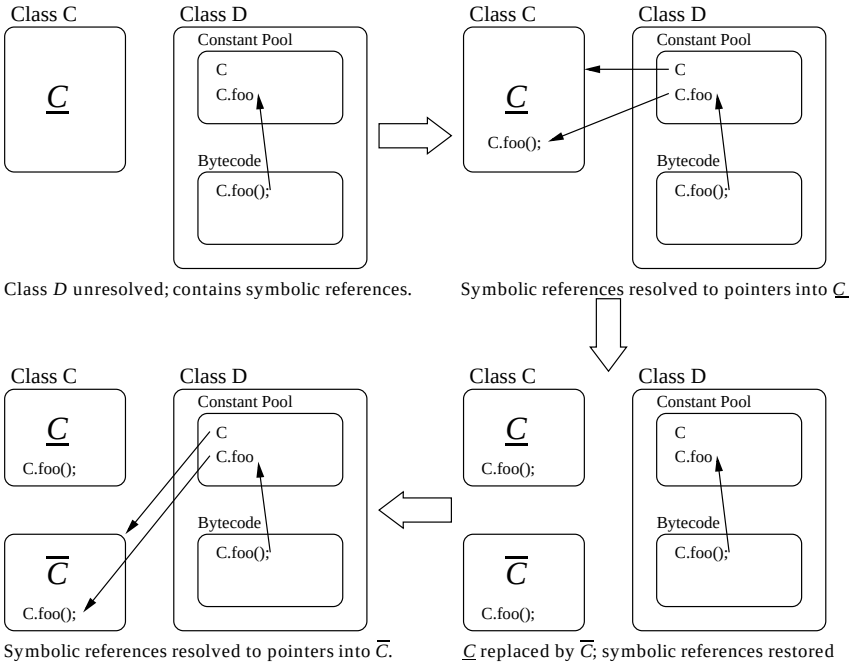

Figure 15: Class objects before and after update.

a class. Classes that contain instances of C as data require no further action. Since Java objects contain references in their component fields and not entire objects, classes are not affected by a change in the class definition of one of their components.

3.4 Pitfalls in Dynamic Classes

The introduction of arbitrary new code into a running Java application has many potentially negative consequences. Type safety may be affected, race conditions may result, etc. Here we consider implementation-level problems and our solutions.

3.4.1 Type Safety

Recall from Section 2 that the operation $\underline{C} \mapsto \overline{C}$ is allowed if it does not cause static or dynamic type violations. Therefore, before making any change, the DVM verifies these conditions. This maintains program correctness and type-dependent security mechanisms.

The DVM checks for static type violations by examining $\underline{C}$, $\overline{C}$, and any dependents. Assume that $\underline{C}$ has a field X, and the switch to $\overline{C}$ removes X. There are two possible cases for invalid references – within C, and in other classes. Since we enforce the constraint that $\overline{C}$ must be a valid class definition, the first case is impossible. Before enacting the change, the DVM resolves $\overline{C}$ and runs through the bytecode verifier. Therefore, whether $\overline{C}$ is a compiled class or was generated on the fly, it cannot contain any references to X. However, we may have another class C_D that is dependent on C and references X. In Section 3.3, we described how to identify dependent classes

quickly by scanning their constant pools. We extend this technique to locate references to deleted fields or methods such as X – the name $C.X$ must be present in C_D's constant pool. If any such references are found, the DVM invokes a user-supplied handler, passing it a list of classes that depend on $\underline{C}$. This handler may then throw an exception, update dependent classes if possible, etc. This step ensures that all classes defined, and thus the program itself, are valid after the change.

Likewise, the DVM checks the second condition by comparing $\underline{C}$ and $\overline{C}$, and recursively examining C's superclasses. If $\underline{C} \stackrel{*}{\sqsubseteq} C_S$ and $\overline{C}$ does not, the DVM searches for any classes that depend on C_S. If any are found, the DVM throws an exception. Similar steps are taken if $\underline{C} \stackrel{*}{\geq}_I T$ and $\overline{C}$ does not. It is a straightforward matter to extract this information from the class object data structures.

3.4.2 Race Conditions in Multithreaded Applications

Multithreaded applications raise the issue of race conditions on the definitions and instances of dynamic classes. During redefinition, the data in $\underline{C}$ and $\overline{C}$ are in an inconsistent, transitory state. If an active thread references C during this time, runtime system errors will likely result. The DVM prevents this event by blocking all threads prior to performing the replacement.

Ideally, the DVM could identify all threads that depend on C, and block only those threads. Unfortunately, this requires a lengthy recursive search of all loaded classes for every frame on every thread stack. This operation is actually much more costly than the class replacement, which is fairly brief. Thus, the DVM blocks all threads except for that performing the change, and allows the threads to continue after the change is complete.

The internal workings of the JVM contain a number of monitors: the heap lock, class loading and linking locks, thread queue lock, etc. We added a new lock, the class replace lock. Any object reference or method invocation bytecode instruction could potentially be involved in a race condition if one of its operands was being modified. Therefore, we instrumented each of these instructions to wait on the class replace lock before continuing. Before modifying a class, the DVM allows all threads to continue until it is unsafe to do so – that is, until they hit an object reference or method invocation instruction. If the DVM did not allow threads to continue in this manner, and blocked them at an arbitrary point by locking the scheduler, race conditions could result if a thread were blocked while in the middle of executing an instruction. The extra checks involved in this instrumentation result in a slight performance penalty.

3.4.3 Native Methods

The JVM allows users to run native methods, and the potential for race conditions during a class change exists here as well. Since native methods do not use a Java stack, and their code cannot be easily examined for dependencies, it is very difficult to determine if it is safe to make a change while a native method is active. Further, native code does not consist of discrete bytecode instruction sections. It is difficult to determine when it is safe to block a native method without causing

race conditions as described above.

One solution is to simply disallow class changes while native methods are active. Unfortunately, many native methods are involved in I/O and include polling loops; they are perpetually active. Therefore, the DVM does not block native threads, nor does it wait for them to finish or reach any particular state before continuing with a class change. There is a danger that a native thread could access some internal data structure while the DVM is modifying a class. However, since the JVM cannot control the execution of native methods, there is always the danger that one will corrupt the runtime state in some manner. We assume that all native methods are trusted to behave properly.

Race conditions during object update are easier to handle. Native methods should "pin" Java objects before accessing them, a form of locking. Before changing a class, the DVM scans the heap and ensures that no instances of that class are pinned.

3.4.4 Changing Active Methods

An interesting problem involves changing a method *that is currently running*. Given a method $C.M$, we must first determine if $C.M$ has changed. Whenever the dynamic class loader loads a class, it calculates and stores a hash value for each method. The DVM can then determine if M has changed by comparing the old and new hash values.

This cannot be done by a simple string compare of $\underline{C}$'s and $\overline{C}$'s versions of M, since the constant pools indices used as arguments in the bytecode may change, even if the method code does not. Any deeper examination of the bytecode becomes costly. So, whenever the dynamic class loader loads a class, it calculates and stores a hash value for each method. This hash value includes all bytecode instructions, and the full names of all classes, methods, and fields referenced, rather than the symbolic references. Then, the DVM can determine if M has changed by comparing the old and new hash values. There is a slight possibility of collision, where two different methods give the same hash value, thus causing a false negative. Therefore, in the event of a match, the DVM also checks other information such as bytecode length and stack size.

Once it has determined that M has changed, the DVM must include $C.M$ in its search of the active thread stacks. Given that M is at an arbitrary point in execution, that Java bytecode contains no semantic information about control flow, and that no particular relationship between $\underline{M}$ and $\overline{M}$ is required, it is impossible, in the general case, to determine where and how to continue execution in $\overline{M}$. For instance, if $\underline{M}$ and $\overline{M}$ solve the same problem using different algorithms, there may not be a point in $\overline{M}$ corresponding to the current location in $\underline{M}$. Or, $\overline{M}$ may use local data that is not present in $\underline{M}$, and that must be initialized. This problem is similar to that posed by security behavior across class changes, as discussed in Section 2.3. Again, heuristics might be used to solve specific cases, but such heuristics are beyond the scope of this paper. Therefore, active methods cannot be changed. If the user attempts to change an active method, the DVM throws an exception, aborting the offending thread. The user may handle this exception in another manner, by continuing the thread but aborting the replacement, terminating and re-invoking the method,

etc.

4 Discussion

In this section, we assess the effectiveness of our approach. First, we discuss library-based support as an alternative to runtime system support. We describe a possible solution, and justify our decision to modify the JVM. We then analyze the performance of the DVM, as compared to the standard JVM. Finally, we survey other work related to dynamic evolution, comparing our design and implementation to the others.

4.1 Library-based Support for Dynamic Classes

In this section, we briefly describe how dynamic classes can be supported using a library-based approach.

We can support a dynamic class by defining a proxy class that presents the interface of a class and wraps its implementation, in a manner similar the wrapper-based approaches described in Section 4.3. For each dynamic class C, we create a *proxy* class, C_{proxy}, and an *implementation* class, C_{imp}. In order to wrap method calls, C_{proxy} contains the interface methods and an array of associated method objects that include the method bodies. For each method defined in C, C_{proxy} contains a wrapper method (W) and a reference to the associated method body (M). W explicitly invokes M, which points to the corresponding method body in C_{imp}. When C's implementation C_{imp} is switched, M is updated to point to the corresponding method object in the new C_{imp}. C_{proxy} also contains a reference to an object of type C_{imp}, whereby instances of C_{proxy} become pseudo-objects of C_{imp}. C_{proxy} must keep a static list of all objects of the type created, and update this list in the constructor. When C_{imp} is switched, C_{proxy} traverses the list of pseudo-objects, switching object references to refer to an object of the new type.

This approach achieves the primary goal of runtime class redefinition. However, it has several drawbacks:

- Dynamic class specification: Although a proxy class may wrap a malleable implementation, the interface of the proxy itself is static. Therefore, the interfaces of dynamic classes cannot change. Subject to these restrictions, use of dynamic classes becomes awkward.

- Semantic properties: The usage of proxies means that some semantic information contained in the original class is lost. For example, C_{proxy} and C_{imp} do not reproduce the inheritance tree associated with C. Hence, proxies may interfere with runtime system capabilities that rely on this semantic information; these include reflection, serialization and casting.

- Efficiency: In the solution we considered, every method call on a dynamic class is instrumented into *two* method calls: one call to the proxy method, and another to invoke the

associated implementation method body. To support pseudo-objects, each class must essentially manage its own instances, imposing an additional layer of object management. The number of classes loaded into the system increases. Essentially, the proxy approach requires that a pseudo-virtual machine run on top of the standard JVM.

- Multithreading: Race conditions can result if one thread modifies a class that another thread is using. The problem recurs with object update. Java's native synchronization methods do not readily support any solution to this synchronization problem.

Modifying the virtual machine itself provides much more flexibility and efficiency. All data structures internal to the VM are available for direct inspection and manipulation, using fast native code. However, this approach has the disadvantage that dynamic classes require use of a specific VM, in this case our modified version of Sun's JDK 1.2.

Although library-based dynamic classes are an interesting topic of research, the inherent technical difficulties and performance issues led us to conclude that the method is simply not practical for the class of applications we target. Modifying the virtual machine proved to be a viable and more effective technique. This approach does, of course, suffer from the limitation that the DVM must be used to run any program that uses dynamic classes. A library-based solution could work with any JVM implementation.

4.2 Performance Analysis

We are concerned with two performance factors: baseline performance of the modified VM, and the cost of replacing a class and updating its instances. We have performed a series of experiments to determine precisely where penalties are incurred and their degree, and to suggest optimizations and improvements. These results pertain to an unoptimized DVM; work on optimization is proceeding apace.

4.2.1 Overhead of adding dynamic classes to JVM

It is straightforward to test the baseline performance of the DVM, simply by running a series of benchmark programs on both the DVM and unmodified JVM. We ran the SpecJVM '98 benchmark suite [44], with a problem size of 100, on a 266 MHz Intel Pentium II running SunOS 5.6. Figure 16 summarizes the results.[5] The performance penalty varied between applications from around five percent to nearly ten, with the average around six percent.

We ran another experiment to determine the penalty caused by each of our modifications. For this experiment, we used a simpler set of benchmark programs [18], run with different versions of the DVM. Each successive DVM version activates an additional instrumentation of the unmodified JVM. Instrumentations include the elimination of quick instructions (see Section 3.1.4), checking if an update is needed in object reference instructions (see Section 3.2), and the class replace lock

[5]These results are not SPEC compliant, and are intended for internal comparison only.

Benchmark program	*JVM*	*DVM*	*JVM/DVM*	*DVM w/ replace*	*no replace/replace*
jess	1420.888	1562.581	90.9%	1738.559	90%
db	2675.772	2932.931	91.2%	3257.733	90%
javac	1692.285	1840.9	91.9%	2181.056	84%
mpegaudio	6383.705	6743.099	94.7%	6853.353	98%
mtrt	1709.399	1883.119	90.8%	2163.25	87%
jack	2083.441	2306.306	90.3%	2559.645	90%
Total	15966.552	17269.977	92.5%	18753.596	92%

Figure 16: SpecJVM benchmark results. All time in seconds.

check for object reference and method invocation instructions (see Section 3.4.2). Figure 17 summarizes the performance cost distribution. The costly modifications are the elimination of quick instructions and the class replace lock; each incurs an approximately 5% penalty. The penalty caused by the object update check is very small. Current efforts focus on reducing these penalties by implementing a more efficient locking mechanism, and possibly re-enabling quick instructions for non-dynamic classes.

These data inform the wide range in performance cost reported in Figure 16. Applications that have a higher proportion of object reference and method invocation bytecode instructions, as compared to other instruction types, suffer more from both the loss of quick instructions and the class replace lock check.

VM version	*time*	*JVM/DVM*	*penalty*
JVM	54.6	–	–
DVM	55.8	97.8%	2.2%
No quick instructions	58.8	92.9%	4.9%
Update object check	58.9	92.7%	0.2%
Class replace lock check	62.4	87.5%	5.2%

Figure 17: Performance cost distribution.

4.2.2 Cost of modifying classes

The acquisition of meaningful data about the cost of replacing a class and updating instances is more complex. Many variables are involved, including the behavior of the application (object allocation and usage, etc.) and the state of the runtime system (number of classes loaded, thread state, etc.). Thus, different applications will generate widely varying data. We have experimentally modelled this cost by running the Spec benchmarks, as above, alongside a thread that periodically replaced a randomly selected user class. We did not modify any Spec classes; any such class is replaced with itself, causing no instance update. We included a "dummy" class that, when changed, has a different implementation. Our extra thread allocates and periodically accesses many instances of this class. The number of objects used in this set of experiments was 10000, and the interval between class changes was 5 seconds – we consider this to be a fairly heavy replace / update load. We show the results in Figure 16. The overall performance penalty ranged from ten to sixteen percent, with average at eight percent.

4.3 Related Work

We survey related work in dynamic evolution in the context of programming models. We loosely classify techniques according to the semantics of changing code, and the programming interface. Other work in dynamic classes is the most pertinent, so we begin there. We then examine other approaches.

4.3.1 Dynamic Classes

Under dynamic classes, the definition of a type may be changed at runtime. However, the defining type of an individual object may not, as is the case with dynamic typing. Any change is applied directly to the type definition rather than its instances. Therefore, objects in memory must somehow be partitioned between different versions of the class, as described in Section 3.2.1.

C++-style templates, at first glance, seem to provide some dynamic capability – a template class or function can change based on what template parameter is provided. However, this is static. Effectively, templates generate new classes during compilation, but cannot generate or modify classes at runtime. The Java interface construct suffers from similar limitations, as discussed under dynamic linking. The Java interface construct is not sufficient either; one may load and use a new implementation class for an existing interface, but any existing instances of the original implementation are not affected.

Hjalmtysson and Gray [21] implement dynamic classes in C++. The system uses a wrapper, or proxy class, method that essentially implements Java / Objective C style interfaces in C++, and further extends the mechanism to allow linking of a new implementation class at runtime, and the presence of multiple active versions. This does not require runtime system support or language extensions, and could be applied to Java as well – the authors chose not to do so for performance reasons. This is similar to the approach presented in Section 4.1, and is subject to the same disadvantages.

Shadows [14] is a system for projecting objects between type spaces, and has been implemented in C++. Shadows also uses a form of proxy class, called a *shadow map*. This map is used to map nodes from the original data structure or type into an extended structure, or *shadow*. Shadows uses runtime type checking to maintain type safety. As with dynamic C++ classes, Shadows does not require compiler or runtime support, but can only be used with specifically coded programs and incurs overhead that might be prohibitive in a Java environment.

Delegation [33] provides a mechanism by which Kniesel [29] implements dynamic classes. Delegation permits *object*- rather than class-based inheritance. A class can contains *delegates*, which are objects invoked to perform certain functions. By changing the delegates bound to a function, one can easily change that function's implementation.

4.3.2 Dynamic Linking

Within most imperative languages such as C++ or Java, name binding and resolution occurs during several stages of program development and execution: compilation, static and dynamic linking, and execution. With static linking, names are bound while building the program, and the binding cannot be changed without relinking. Dynamic linking [22, 27, 12] allows names to be bound when the program begins execution. Once done, this binding cannot be changed without restarting the program. The common point among all traditional stages of binding is that any type or method name can only be bound *once* across all phases. Further, dynamic linking contains no notion of state or correctness. Even if it were possible to re-link a dynamic library, there is no semantic framework dictating how and when it may be done.

Java's native dynamic capabilities are based on dynamic linking using the class loader [31]. The classes used by a program are not loaded and resolved until they are needed. Therefore, different versions of a class may be used in different runs of the program. However, although classes may be loaded dynamically after startup, a class cannot be reloaded after objects have been instantiated.

4.3.3 Loadtime Transformation

Several projects exist that support modification or generation of classes at loadtime (before or during class loading). This technique can be used to optimize or reconfigure applications by generating and loading specialized classes. However, the method is subject to the limitations of dynamic linking. New classes can be generated and loaded, but classes and objects previously present in the JVM are not affected. Classes can change in the static or loaded state, but not while active. Linguistic reflection [28], Binary Component Adaptation [26] and JOIE [8] implement loadtime transformation.

4.3.4 Dynamic Architectural Frameworks

Architectural frameworks such as Corba [1], COM [5] and C2 [45] provide a mechanism by which a program can be described in terms of high-level components such as modules and connectors. In general these frameworks are static – once defined, a program is static and its design cannot be changed at runtime. Dynamic frameworks allow the user to change the high-level architectural specification of a program at runtime.

Archstudio [37] provides graphical and command-line tools used to modify a C2-Java program specification at runtime. An attempt to change the specification invokes an Architecture Evolution Manager, which checks the request for validity, and modifies the program's implementation accordingly.

The Argus language [34], which provides a client/server model for distributed computing, supports dynamic update of servers, or guardians [4]. Similarly, Conic [35] provides a module-based environment using message passing. Modules communicate via ports, and may be dynam-

ically updated by switching all links from the present version of a module to a new one. However, the ports between modules are static, thus connections cannot be created or broken dynamically.

The disadvantage of dynamic architectures is that they require that target programs be written using a specific framework or language. Also, changes are generally restricted to a fairly high level. If changes are specified in terms of large components, then making incremental changes to those components becomes awkward.

4.3.5 Dynamic Typing

CLOS [43] and Smalltalk [15] support dynamic typing, in which the type descriptor of an object may be changed freely at runtime. Method code may be modified, data fields and methods may be added or removed, etc. For example, the Information Bus [36] distributed systems architecture uses a CLOS-derived language to implement dynamic classes. Fabry [11] implements a dynamic type system using capabilities. Widening [42] provides a mechanism for *constrained* dynamic type changes, in which objects may be temporarily "widened" to a subtype of their defining class. [9] implement a mechanism similar to widening, for imperative languages, and present a formal type system with proof of soundness.

Dynamic typing, in its unconstrained form, supports the greatest flexibility. However, static type checking of any kind becomes infeasible, so the runtime system must support complete runtime type checking, with all associated overhead.

4.3.6 Higher Order Functions

Functional languages such as Lisp [43] implement *higher order functions*. A function in Lisp is simply a list, and may be manipulated just as any other data structure. Thus, function transformation is a major part of programming in Lisp. Its semantics are rigorously and clearly defined using lambda calculus. First order functions are generally restricted to functional languages, and it is difficult to implement them in a runtime system that does not support direct interpretation, e.g. C++ or Java. Further, the model is limited to changing code, not data types. Function pointers, supported in C++, provide a rough form of first order functions, but lack the flexibility of Lisp. Some operating systems allow programs to write their own code segment, another approximation of first order functions. For the obvious security-related reasons this approach is not commonly used.

4.3.7 Parallel Versions

One approach to replacing one version of a program ($\underline{P}$) with a new version ($\overline{P}$) is to beginning running *both* versions in parallel, transferring $\underline{P}$'s state to $\overline{P}$ at an appropriate time. Both software and hardware-based solutions exist. Gupta and Jalote [19] use processes as update vectors, and SCP [41] uses redundant CPUs.

While efficient, redundant hardware is obviously expensive, and only practical in certain situations such as the telecommunications environment towards which SCP is targeted. Parallel processes are an efficient technique. However, transfer of state, which may include open files, displays, and elements not affected directly by the change, can be awkward.

5 Conclusion

We have described the design and implementation of dynamic classes in Java, using runtime support. Our solution is novel in the combination of type safety preservation, nearly unrestricted changes, support for any Java class, and efficiency. These features balance efficiency, convenience, safety, and power of expression.

We have developed a dynamic security infrastructure using dynamic classes [20], as well a mechanism that enhances the dynamism of JDK 1.2's native security model, as described in Section 2.4. We are also working on a dynamic architectural framework based on Java Beans [23], and a code distribution mechanism similar to that outlined in Section 2.4. These applications, in conjunction with our performance analysis, show that dynamic Java classes are a useful language extension that supports an exciting class of software. Further optimization of the DVM is an ongoing process.

Currently, our primary focus for future work is the extension of the dynamic classes model to distributed systems. The introduction of distributed applications running across multiple hosts, with objects migrating between them, has many implications. For example, due to latency and packet dropping over the network, our current synchronization model does not scale well to multiple hosts. It is difficult to avoid race conditions while maintaining efficiency. One solution is to simply accept race conditions and work around them. This approach implicitly creates a multiple-version model of classes, which merits further contemplation.

6 Software

The DVM is available for Solaris and Linux. For details, see `http://pdclab.cs.ucdavis.edu/`.
